Abstract—Integrated sensing and communication (ISAC) has been proposed as a promising paradigm in the future wireless networks, where the spectral and hardware resources are shared to provide a considerable performance gain. It is essential to understand the sensing and communication (S&C) influence on each other to guide the practical algorithm and system design in ISAC. In this paper, we investigate the performance tradeoff between S&C in a single-input single-output (SISO) ISAC system with finite blocklength. In particular, we present the system model and the ISAC scheme after which the tradeoff is studied to obtain the performance metric. Then we derive the achievability and converse bounds for the rate-error tradeoff of estimating the location of the joint S&C performance. Furthermore, we develop the asymptotic analysis at large blocklength regime, where the performance tradeoff between S&C is proved to vanish as the blocklength tends to infinity. Finally, our theoretical analysis is consolidated by simulation results.

Index Terms—Integrated sensing and communication, finite blocklength, rate-error tradeoff, asymptotic analysis

I. Introduction

Recent years have witnessed the rapid development of 5G technologies in modern civil and military applications such as intelligent vehicular networks and drone operations, which leads to the severe congestion of the spectrum and hardware resources [1]. To improve the resource utilization and reduce cost, ISAC is emerging as a key technique in the next generation wireless networks [2]–[4]. Compared with the traditional wireless networks, ISAC applies the integrated signal type, which leads to the significant cost saving when the performance is limited by the sharing of spectrum and hardware resources from the sharing of spectrum and hardware.

There exist many crucial problems in the ISAC research including the theoretical framework, the system protocol and the signal processing algorithm [5]. The most important and challenging among them is the characterization of the performance tradeoff between S&C, which comes from the signal sharing in ISAC [6]. In ISAC, the purpose of communication is to transmit information, while the purpose of sensing is to detect the environment, which is to improve the performance of the system. The performance tradeoff analysis can provide a contribution

to understanding the fundamental limits of the dual functions and to guide the design and operation of practical ISAC systems. Therefore, extensive works have been dedicated to address this issue.

In [2], the authors characterize the capacity-distortion tradeoff of the ISAC system with sensing referring to the state estimation based on the state-dependent channel feedback, and a modified Blind-Arithmetic is proposed, which is empirically depicted the tradeoff between the performance tradeoff between the radar and the communication, and this investigation ISAC system, the bound of the probability rate regions are derived. Recently, the authors in [7] have determined the S&C performance at the corner point of the ORB region to reveal a point of the GRB. ISAC regions reveal a two-fold tradeoff in ISAC systems.

Although progress has been made in terms of establishing the theoretical foundation of ISAC, there exists a common limitation in the above studies. Most existing works use Shannon channel capacity as the performance metric for the communication rate, which is an asymptotic result with the blocklength approaching infinity. However, the evaluation of performance is meaningless with infinite blocklength since the estimation error tends to zero with infinite signal length. In this paper, we analyze the performance tradeoff between S&C in the finite blocklength regime, which motivates our work.

In this paper, we characterize the performance tradeoff between S&C in a SISO ISAC system with finite blocklength. First, in Section II, we present the system model including the ISAC scheme and performance metrics, where the rate-error region is defined to evaluate the tradeoff. Then, in Section III, we derive the achievability and converse bounds for the rate-error tradeoff, after which the asymptotic analysis is performed to show that the tradeoff vanishes as the blocklength increases. In Section IV, the theoretical results are verified by the numerical experiments. Finally, Section V concludes this paper.

II. SYSTEM MODEL

In this section, we first present our signal model and ISAC scheme, then we define the performance metrics for communication

Fig. 1: The block diagram of our proposed ISAC Scheme, which consists of the message decoding step and the communication-assisted estimation step.

tion and sensing are introduced to characterize the rate-error tradeoff. Furthermore, communication and sensing are introduced to characterize the rate-error tradeoff.

Consider a SISO ISAC signal model given by

$$\mathbf{y} = \mathbf{h}\mathbf{x} + \mathbf{n} \quad (1)$$

where $\mathbf{x} \in \mathbb{C}^N$ is the transmitted random communication symbol and N denotes the blocklength. The notation \mathbb{C}^N denotes a N -dimensional complex Euclidean space where the dimension N is measured with respect to the real dimension. We denote \mathbb{R}^N as the N -dimensional real Euclidean space. We denote $\mathbf{y} \in \mathbb{C}^N$ as the received signal and $\mathbf{n} \in \mathbb{C}^N$ as the additive Gaussian noise with zero mean, i.e., $\mathbf{n} \sim \mathcal{CN}(\mathbf{0}, \sigma^2 \mathbf{I}_N)$. The sensing parameters, which is assumed to be constant in all N channel uses since the sensing parameters such as target positions and velocities are constant during the communication process in most ISAC systems. The goal of ISAC is to simultaneously recover the communication message and estimate the sensing parameters based on the dual-functional signal.

To analyze the performance trade-off between S&C, we first present the mathematical formulation for our ISAC system, which is based on a two-step scheme including message decoding and communication-assisted estimation shown in Fig. ??.

The message-decoding step aims to recover the transmitted communication symbol based on the received signal $\mathbf{y}(\mathbf{x}, h)$, which determines the communication performance of our ISAC system. In particular, we apply the (N, M, ϵ) code introduced in [?], which includes

- 1) A message set $\mathcal{M} = \{1, 2, \dots, M\}$ with equiprobable messages,
- 2) An encoder which maps the message $m \in \mathcal{M}$ to the codewords $\mathbf{x}_m \in \mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\}$. We assume that the channel gain is confined to a certain set, i.e., $|h| \in [|h|_L, |h|_U]$, which is known to the encoder¹. The

- 1) A message set $\mathcal{M} = \{1, 2, \dots, M\}$ with equiprobable messages,
- 2) An encoder which maps the message $m \in \mathcal{M}$ to the codewords $\mathbf{x}_m \in \mathcal{X} = \{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_M\}$. We assume that the channel gain is confined to a certain set, i.e., $|h| \in [|h|_L, |h|_U]$, which is known to the encoder¹. The

notation $|\cdot|$ denotes the absolute value of the complex number. Therefore, the encoder can be expressed by

$$f: \mathcal{M} \times \mathbb{R}^2 \rightarrow \mathcal{X}, \quad m \times [|h|_L, |h|_U] \rightarrow \mathbf{x}_m. \quad (2)$$

Furthermore, the codewords satisfy the power constraint

$$f: \mathcal{M} \times \mathbb{R}^2 \rightarrow \mathcal{X}, \quad m \times [|h|_L, |h|_U] \rightarrow \mathbf{x}_m. \quad (2)$$

Furthermore, the codewords satisfy the power constraint

$$\|\mathbf{x}_m\|^2 \leq N\rho, \quad i = 1, \dots, M \quad (3)$$

where the constant ρ is the per-codeword power budget;

3) A decoder which maps the received signal to the message, i.e.,

$$g: \mathbb{C}^N \rightarrow \mathcal{M}, \quad \mathbf{y} \rightarrow m. \quad (4)$$

Furthermore, the decoder satisfies

$$\mathbb{P}\{g(\mathbf{y}) \neq m\} \leq \epsilon. \quad (5)$$

where $\mathbb{P}(X)$ denotes the probability of the random set X .

Furthermore, the decoder satisfies

$$\mathbb{P}\{g(\mathbf{y}) \neq m\} \leq \epsilon. \quad (5)$$

The communication-assisted estimation step aims to estimate the sensing parameters based on the received signal, which determines the sensing performance of our ISAC system.

For simplicity of analysis, we focus on the estimation of the channel coefficient itself in this paper, while the analysis of estimating general sensing parameters is left for our future work.

In particular, we first reconstruct the communication symbol $\hat{\mathbf{x}} = g(\mathbf{y})$. Then we apply a maximum-likelihood (ML) estimator to estimate the channel coefficient. Since this ML estimator can asymptotically achieve the Cram er-Rao lower bound [?], after some algebra work, we obtain that

we first reconstruct the communication symbol as $\hat{\mathbf{x}} = g(\mathbf{y})$.

Then we apply a maximum-likelihood (ML) estimator (6) to estimate the channel coefficient since the ML estimator

achieves the minimum variance unbiased estimation (MVUE) of the channel coefficient. The ML estimator can asymptotically achieve the Cram er-Rao lower bound [?]. After some algebra work, we obtain that

we first reconstruct the communication symbol as $\hat{\mathbf{x}} = g(\mathbf{y})$.

Then we apply a maximum-likelihood (ML) estimator (6) to estimate the channel coefficient since the ML estimator

achieves the minimum variance unbiased estimation (MVUE) of the channel coefficient. The ML estimator can asymptotically achieve the Cram er-Rao lower bound [?]. After some algebra work, we obtain that

When both the communication and sensing performance are taken into consideration, we define the rate-error region as the communication rate for the (N, M, ϵ) code, i.e.,

$$\mathcal{F}(N, \epsilon) \triangleq \left\{ (R, \epsilon) : \exists (N, M, \epsilon) \text{ code} \right\} \quad (9)$$

$$R = \frac{\log_2 M}{N} : \exists (N, M, \epsilon) \text{ code}. \quad (7)$$

which collects all the feasible pairs of the communication rate and sensing error achieved by the (N, M, ϵ) code. Then the boundary of $\mathcal{F}(N, \epsilon)$ reveals the optimal performance of communication or sensing when the other one meets certain minimum requirements, which characterizes the performance tradeoff. Therefore, we focus on determining the boundary of the rate-error region in the following sections of this paper. Namely, we aim to obtain

When both the communication and sensing performance are taken into consideration, we define the rate-error region as

where D denotes the minimum requirements for the sensing performance, and R^* denotes the rate-error tradeoff. When D tends to infinity, the rate-error tradeoff approaches the maximal achievable rate of the quasi-static channel regardless of sensing performance, i.e.,

Then the boundary of $\mathcal{F}(N, D)$ reveals the optimal performance of communication or sensing when the other one meets certain minimum requirements, which characterizes the performance tradeoff. Therefore, we focus on determining the boundary of the rate-error region in the following sections of this paper. Namely, we aim to obtain

Remark 1: In most existing researches on the performance tradeoffs between S&C, the influence of the blocklength N and the probability of decoding error ϵ are not taken into consideration since the estimation error σ^2 is independent of the decoder outputs where communication and sensing are separately performed at the receiver and the transmitter, the sensing performance is not affected. However, when dual functionalities are required at the receiver concurrently, such as in the intelligent vehicular networks and other cooperative applications, existing tradeoff analysis is inapplicable. As will be shown later, the blocklength and the probability of decoding error induce a tighter connection for S&C and require in-depth rate-error analysis.

which has been widely investigated in the communication theory [7], [11], [2].

III. RATE-ERROR TRADEOFF ANALYSIS

Remark 1: In most existing researches on the performance tradeoff between S&C, the influence of the blocklength N and the probability of decoding error ϵ are not taken into consideration since the estimation error is independent of the decoder outputs where communication and sensing are separately performed at the receiver and the transmitter, respectively [7], [11], [2]. However, when dual functionalities are required at the receiver concurrently, such as in the intelligent vehicular networks and other cooperative applications, existing tradeoff analysis is inapplicable. As will be shown later, the blocklength and the probability of decoding error induce a tighter connection for S&C and require in-depth rate-error analysis.

which has been widely investigated in the communication theory [7], [11], [2].

In this section we characterize the rate-error tradeoff in our ISAC systems. Note that even the exact expression of the maximal achievable rate regardless of sensing performance is intractable with a fixed blocklength and the probability of decoding error. We derive the achievability (lower) and converse (upper) bound of R^* to characterize the performance tradeoff between S&C, and discuss the asymptotic property of these two bounds when the blocklength N tends to infinity.

A. Achievability Bound

In this subsection, we present the achievability bound of the rate-error tradeoff $R^*(N, \epsilon, D)$.

First, we tighten the inequality power constraint (??) into the equality one, i.e., $\|x_i\|_2^2 = N\rho$, $i = 1, \dots, M$. We denote by $\mathcal{W} \subseteq \mathcal{S}^N$ the set of the codewords.

Proposition 1: For the (N, M, ϵ) code with the tightened power constraint, the rate-error tradeoff must be a lower bound

of $R^*(N, \epsilon, D)$. Furthermore, whatever regardless the sensing performance is, regardless of sensing performance, it is proved that [3] decoding error. We derive the achievability (lower) and converse (upper) bound of R^* to characterize the performance tradeoff between S&C, and discuss the asymptotic property of these two bounds when the blocklength N tends to infinity.

Therefore, we only need to determine the achievability bound for $R^*(N, \epsilon, D)$.

A. Achievability Bound

where the codewords are distributed on the complex hypersphere $\mathcal{S}^N = \{x \in \mathbb{C}^N : \|x\|_2^2 = N\rho\}$. Then we investigate the relationship between the MSE given by (??) and the feasible set of the codewords. In particular, given a set $\mathcal{W} \subseteq \mathcal{S}^N$, i.e., $\|x_i\|_2^2 = N\rho$, $i = 1, \dots, M$, we introduce the definition of the maximal bias as follows.

Definition 1: The maximal bias with respect to a subset $\mathcal{W} \subseteq \mathcal{S}^N$ is defined as

$$\Delta_W \triangleq \sup_{x \in \mathcal{W}} \left| \frac{1}{N\rho} \sum_{i=1}^N x_i^2 \right| \quad (13)$$

Remark 2: Recalling the expression shown in (??), we find that Δ_W equals to the maximum mean error of any ML estimator with both the transmitted symbol x and the reconstructed symbol \hat{x} distributed in the set \mathcal{W} . Therefore, the maximal bias characterizes the diversity of the codewords distributed on the complex hypersphere $\mathcal{S}^N = \{x \in \mathbb{C}^N : \|x\|_2^2 = N\rho\}$ which attains the maximum value $\Delta_W = 2$ with $\mathcal{W} = \mathcal{S}^N$ and the minimum value $\Delta_W = 0$ with \mathcal{W} as any single point set.

In particular, given a set $\mathcal{W} \subseteq \mathcal{S}^N$, we introduce the definition of the maximal bias as follows.

Definition 1: The maximal bias with respect to any subset $\mathcal{W} \subseteq \mathcal{S}^N$ is defined as

$$\Delta_W \triangleq \sup_{x \in \mathcal{W}} \left| \frac{1}{N\rho} \sum_{i=1}^N x_i^2 \right| \quad (13)$$

Remark 2: Recalling the expression shown in (??), we find that Δ_W equals to the maximum mean error of any ML estimator with both the transmitted symbol x and the reconstructed symbol \hat{x} distributed in the set \mathcal{W} .

Remark 3: According to proposition ??, the upper bound of MSE can be divided into two parts: the first part refers to the sensing performance in the bias term, where the reconstructed symbol equals to the transmitted communication symbol. The second part refers to the sensing performance with decoding error, which consists of the bias term and the cross term since \hat{x} is not an unbiased estimator of x with $x \neq \hat{x}$. In the radar-based ISAC systems where the transmitted symbol is known to the estimator, i.e., $\epsilon = 0$, we obtain that $\text{MSE} = \sigma^2/N\rho$ which coincides with the existing theoretical results.

Then we can derive an upper bound of the MSE when the codewords are distributed in the set \mathcal{W} which is formulated as the following proposition.

Proposition 1: For the (N, M, ϵ) code where the codewords are distributed in the set $\mathcal{W} \subseteq \mathcal{S}^N$, the MSE for the ML estimator is upper-bounded by

$$\text{MSE} \leq \frac{\sigma^2}{N\rho} + \epsilon \frac{\sqrt{N\rho}}{N\rho} \Delta_W^2 + \frac{2\sigma\sqrt{N\rho}}{N\rho} \Delta_W \quad (14)$$

where the first term is the sensing performance in the ideal case where the reconstructed symbol equals to the transmitted symbol.

Remark 3: According to proposition ??, the upper bound of MSE can be divided into two parts: the first part refers to the sensing performance in the bias term, where the reconstructed symbol equals to the transmitted communication symbol. The second part refers to the sensing performance with decoding error, which consists of the bias term and the cross term since \hat{x} is not an unbiased estimator of x with $x \neq \hat{x}$. In the radar-based ISAC systems where the transmitted symbol is known to the estimator, i.e., $\epsilon = 0$, we obtain that $\text{MSE} = \sigma^2/N\rho$ which coincides with the existing theoretical results.

Then we can derive an upper bound of the MSE when the codewords are distributed in the set \mathcal{W} which is formulated as the following proposition.

Proposition 1: For the (N, M, ϵ) code where the codewords are distributed in the set $\mathcal{W} \subseteq \mathcal{S}^N$, the MSE for the ML estimator is upper-bounded by

$$\text{MSE} \leq \frac{\sigma^2}{N\rho} + \epsilon \frac{\sqrt{N\rho}}{N\rho} \Delta_W^2 + \frac{2\sigma\sqrt{N\rho}}{N\rho} \Delta_W \quad (14)$$

where the first term is the sensing performance in the ideal case where the reconstructed symbol equals to the transmitted symbol.

where $\tilde{R}_{\text{com}}^L(N, \epsilon)$ denotes the maximal achievable rate for the sensing performance with the tightened power constraint which has been investigated in [2], [3]. The threshold D_m is given by $D_m = \frac{\sigma^2}{N\rho}$ with $\hat{\mathbf{x}} \neq \mathbf{x}$. In the radar-based ISAC systems where the transmitted symbol is known to the estimator, i.e., $\frac{\sigma^2}{N\rho} = 0$, we obtain that $\text{MSE} = \sigma^2/N\rho$ which coincides with the existing theoretical results.

With Proposition 2, we only need to derive the achievability bound in the case $D < D_m$ which is shown in the following proposition.

Proposition 3: For $\sigma^2/N\rho < D < D_m$, the rate-error tradeoff $R^*(N, \epsilon, D)$ is lower-bounded by

$$R^*(N, \epsilon, D) \geq \max\{R_{\text{com}}^L(N, \epsilon) + \frac{\gamma_L}{2N}, 0\} \quad (17)$$

where $\gamma_L \in (0, 1)$ is given by

$$\tilde{R}^*(N, \epsilon, D) \triangleq \tilde{R}^*\left(\frac{1}{2}, 1, \frac{2N-1}{2}\right) \frac{1}{R_{\text{com}}^L(N, \epsilon)}, \quad \forall D \geq D_m \quad (18)$$

The function $I_1(a, b)$ is the regularized incomplete beta function. $R_{\text{com}}^L(N, \epsilon)$ denotes the maximal achievable rate regardless of the sensing performance with the tightened power constraint, which has been investigated in [2], [3].

The threshold D_m is given by $D_m = \frac{\sigma^2}{N\rho}$ where the maximal bias Δ_{W_L} is given by $\Delta_{W_L} = \frac{4\sigma\sqrt{\epsilon}|h|U}{\sqrt{DN\rho} - \sigma}$.

With Proposition 3, we only need to derive the achievability bound in the case $D < D_m$, which is shown in the following proposition.

Proposition 4: For $\sigma^2/N\rho < D < D_m$, the rate-error tradeoff $R^*(N, \epsilon, D)$ is lower-bounded by

Sketch of Proof: As for the analysis of the achievability bound, we guarantee the sensing performance through constraining the feasible set of the (N, M, ϵ) codewords, which is shown in Fig. 2(a). In particular, the codewords can take values on the entire hypersphere with $D \geq D_m$, which implies that $R^L(N, \epsilon, D) = R_{\text{com}}^L(N, \epsilon)$. When there exists $\sigma^2/N\rho \leq D < D_m$, we restrict the codewords to the set $\mathcal{W} \subset S^N$ with $\Delta_{W_2} \leq \Delta_{W_1}/2$ to meet the minimum sensing performance requirement, where the largest feasible set \mathcal{W} is a hyperspherical cap. The coefficient γ_L can be viewed as the area ratio of the hyperspherical cap to the hypersphere. Details are omitted due to the lack of space. \square

Remark 4: With Proposition 2 and 3, we can obtain the achievability bound for the rate-error tradeoff $R^*(N, \epsilon, D)$. We denote by $R_{\text{com}}^L(N, \epsilon)$ as the achievability bound of $\tilde{R}^*(N, \epsilon)$ determined by $\frac{\sqrt{DN\rho} - \sigma}{2N}$, the expression of which is provided in [2]. Then the achievability bound $R^L(N, \epsilon, D)$ of $R^*(N, \epsilon, D)$ is given by

Specifically, there exists $\tilde{R}^*(N, \epsilon, D) = 0$ for $0 \leq D \leq \frac{\sigma^2}{N\rho}$.

Sketch of Proof: As for the analysis of the achievability bound, we guarantee the sensing performance through constraining the feasible set of the (N, M, ϵ) codewords, which is shown in Fig. 2(a). In particular, the codewords can take values on the entire hypersphere with $D \geq D_m$, which implies that $R^L(N, \epsilon, D) = R_{\text{com}}^L(N, \epsilon)$. When there exists $\sigma^2/N\rho \leq D < D_m$, we restrict the codewords to the set $\mathcal{W} \subset S^N$ with $\Delta_{W_2} \leq \Delta_{W_1}/2$ to meet the minimum sensing performance requirement, where the largest feasible set \mathcal{W} is a hyperspherical cap. The coefficient γ_L can be viewed as the area ratio of the hyperspherical cap to the hypersphere. Details are omitted due to the lack of space. \square

Remark 4: With Proposition 2 and 3, we can obtain the achievability bound for the rate-error tradeoff $R^*(N, \epsilon, D)$. Then the achievability bound $R^L(N, \epsilon, D)$ of $R^*(N, \epsilon, D)$ is given by

Fig. 2: Geometric illustrations of the achievability and converse bounds. (a) For the achievability bound, the sensing performance constraint constrains the original hypersphere (world sphere) to the feasible set (feasible sphere) Δ (cap) for the converse bound, the maximal bound obtained by packing the Voronoi region packing sphere of radius r_1 into the signal space (radius r_2) is smaller than the black sphere of radius r_1 and r_2 .

Note that the MSE of the ISAC system is lower-bounded by the largest feasible set \mathcal{W} is a hyperspherical cap. The coefficient γ_L can be viewed as the area ratio of the hyperspherical cap to the hypersphere. Details are omitted due to the lack of space. \square

Remark 4: With Proposition 2 and 3, we can obtain the achievability bound for the rate-error tradeoff $R^*(N, \epsilon, D)$. We denote by $R_{\text{com}}^L(N, \epsilon)$ as the achievability bound of $\tilde{R}^*(N, \epsilon)$ determined by $\frac{\sqrt{DN\rho} - \sigma}{2N}$, the expression of which is provided in [2]. Then the achievability bound $R^L(N, \epsilon, D)$ of $R^*(N, \epsilon, D)$ is given by

Specifically, there exists $\tilde{R}^*(N, \epsilon, D) = 0$ for $0 \leq D \leq \frac{\sigma^2}{N\rho}$.

Sketch of Proof: As for the analysis of the achievability bound, we guarantee the sensing performance through constraining the feasible set of the (N, M, ϵ) codewords, which is shown in Fig. 2(a). In particular, the codewords can take values on the entire hypersphere with $D \geq D_m$, which implies that $R^L(N, \epsilon, D) = R_{\text{com}}^L(N, \epsilon)$. When there exists $\sigma^2/N\rho \leq D < D_m$, we restrict the codewords to the set $\mathcal{W} \subset S^N$ with $\Delta_{W_2} \leq \Delta_{W_1}/2$ to meet the minimum sensing performance requirement, where the largest feasible set \mathcal{W} is a hyperspherical cap. The coefficient γ_L can be viewed as the area ratio of the hyperspherical cap to the hypersphere. Details are omitted due to the lack of space. \square

Remark 4: With Proposition 2 and 3, we can obtain the achievability bound for the rate-error tradeoff $R^*(N, \epsilon, D)$. We denote by $R_{\text{com}}^L(N, \epsilon)$ as the achievability bound of $\tilde{R}^*(N, \epsilon)$ determined by $\frac{\sqrt{DN\rho} - \sigma}{2N}$, the expression of which is provided in [2]. power. According to the hypothesis testing theory, the optimal decoder with equiprobable messages is the maximum-likelihood decoder, the decoding regions of which are called the Voronoi regions [?]. Then Proposition ?? is inspired from the idea of sphere packing where the Voronoi region is treated as the hyperball with radius r_c . As is shown in Fig. 2(b), the first inequality in (??) is obtained by the sphere packing within the hyperspherical shell of radius r_1 and r_2 , while the second one is obtained by the sphere packing within the entire hyperball of radius r_1 . Details are omitted due to the lack of space.

Remark 5: Proposition ?? provides a converse bound of the rate-error tradeoff $R^U(N, \epsilon, D)$ which takes the influence of D into consideration. However, $R^U(N, \epsilon, D)$ is nearly independent of D with large N since the term $\log_2(1 - \gamma_U^{2N})$ decays exponentially with the blocklength, which equals to the following inequality holds

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = 2 \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (27)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) \approx R_{\text{com}}^U(N, \epsilon) = 2 \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (28)$$

where $R_{\text{com}}^U(N, \epsilon)$ is the complex hyperball with radius r_c , i.e. $R_{\text{com}}^U(N, \epsilon) = \{x \in \mathbb{C}^N : \|x\|_2 \leq r_c\}$. Therefore, the derivation of a tighter converse bound is still needed to give a more accurate characterization on the performance tradeoff between S&C, which is a challenge to the future work.

C. Asymptotic Analysis

In this subsection, we present the asymptotic analysis for the achievability and converse bounds of the rate-error tradeoff R^U when the blocklength N tends to infinity. As is shown in Fig. 2(b), the first inequality in (??) is bounded by the sphere packing within the hyperspherical shell of radius r_1 and r_2 , while the second one is obtained by the sphere packing within the entire hyperball of radius r_1 . Details are omitted due to the lack of space.

Remark 5: Proposition ?? provides a converse bound for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (29)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) \approx R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (30)$$

where $R_{\text{com}}^U(N, \epsilon)$ is the complex hyperball with radius r_c , i.e. $R_{\text{com}}^U(N, \epsilon) = \{x \in \mathbb{C}^N : \|x\|_2 \leq r_c\}$. Therefore, the derivation of a tighter converse bound is still needed to give a more accurate characterization on the performance tradeoff between S&C, which is a challenge left as our future work.

Therefore, the asymptotic expression of the converse bound $R^U(N, \epsilon, D)$ is given by

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (31)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) \approx R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (32)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (33)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (34)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (35)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (36)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (37)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (38)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (39)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (40)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (41)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (42)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

$$\lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = \lim_{N \rightarrow \infty} R_{\text{com}}^U(N, \epsilon) = \log_2(1 + \frac{N \rho |h|_U^2}{\sigma^2}) \quad (43)$$

for any $\epsilon \in (0, 1/2)$. Note that there exists $\lim_{N \rightarrow \infty} D_m = 4\epsilon |h|_U^2$ according to (??). We can obtain

Fig. 3: The achievability and converse bounds for the rate-error tradeoff with varying code blocklength.

According to the above theoretical analysis, we find that the performance tradeoff between S&C vanishes as the blocklength N increases. We provide a simple interpretation for this phenomenon. Consider an ISAC system where the (N, M, ϵ) code consists of two parts: the first part of length \sqrt{N} is fixed as the pilot data while the other part of length $N - \sqrt{N}$ is treated as the communication data. The sensing performance of this ISAC system should at least achieve $D_0 = \sigma^2 / \sqrt{N} \rho$, which is the MSE of the channel coefficient h obtained from the pilot data only. As N tends to infinity, we have $D_0 \rightarrow 0$ which implies that the sensing requirement can always be met by the pilot data with large blocklength N . Note that the pilot data of length \sqrt{N} will not influence the maximal communication rate asymptotically since there exists $\lim_{N \rightarrow \infty} \sqrt{N}/N = 0$. We find that the S&C performance are decoupled when the blocklength N tends to infinity. Furthermore, it can be seen that the asymptotic expressions of the achievability and converse bound depend on the range of the channel gain, i.e., $|h|_L$ and $|h|_U$. When we have more accurate prior knowledge of the channel gain under the assistance of sensing, the interval $[|h|_L, |h|_U]$ approaches to the true channel gain $|h|_0$ which also implies that the achievability and converse bound coincides, i.e.,

$$\lim_{N \rightarrow \infty} R^L(N, \epsilon, D) = \lim_{N \rightarrow \infty} R^U(N, \epsilon, D) = C \quad (32)$$

where $C = \log_2(1 + \rho |h|_0^2 / \sigma^2) = \log_2(1 + \text{SNR})$ is the Shannon channel capacity.

First, we verify the effectiveness of the achievability and converse bounds derived for the rate-error tradeoff $R^U(N, \epsilon, D)$. Consider the signal modulation by (??) where the power budget P and the noise variance σ^2 are set as $P = 1$ and $\sigma^2 = 1$, respectively. The channel gain is assumed to belong to the effectiveness of [1]. The achievability and converse bounds are derived for the rate-error tradeoff $R^U(N, \epsilon, D)$ with varying blocklength N is shown in Fig. 22. The performance of the proposed power budget and noise

IV. Simulation Results

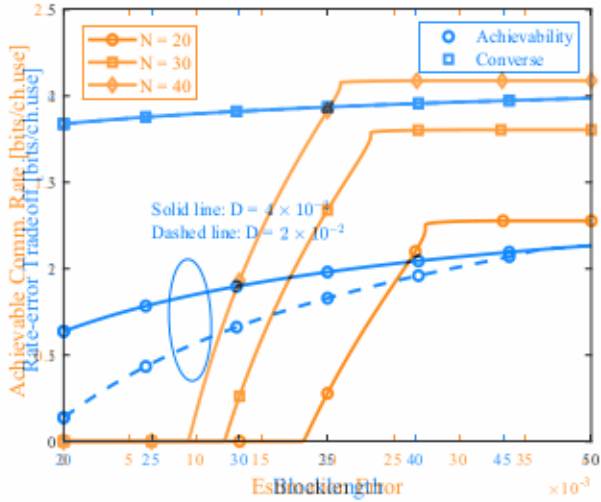

Fig. 3: The achievable rate-error regions with bounds for the blocklength tradeoff with varying code blocklength

sensing performance is set to be $D = 4 \times 10^{-2}$ and 2×10^{-2} , variance are set as $\rho = 10$ and $\sigma = 1$, respectively. The channel gain is assumed to belong to the set $|h| \in [1, 1.5]$.

According to Fig. ??, we find that the converse bounds always outperform the achievability bounds, which is invariant with the sensing performance D since the loss term almost vanishes according to our theoretical analysis. As for the achievability bounds, the rate-error tradeoff increases as D increases since the sensing constraint is relaxed. When N is large enough, the S&C performance is decoupled, which implies that the two achievability bounds converge to the same value $R_{\text{th}}^{\text{S&C}}(N, \epsilon)$.

According to Fig. ??, we find that the converse bounds always outperform the achievability bounds, which is invariant with the sensing performance D since the loss term almost vanishes according to our theoretical analysis.

As then we calculate the rate-error region $\mathcal{F}(N, \epsilon)$ numerically, which are based on the achievability bound since it can provide a more accurate characterization of the performance tradeoff between S&C than the converse bound. The system parameters are set the same as above. The achievable rate-error region is shown in Fig. ?? with the blocklength set to be $N = 20, 30, 40$, respectively.

According to Fig. ??, we find that as D increases, the achievable rate-error region expands. When D exceeds the threshold bigger than $\sigma^2/N\rho|h|^2$, the achievable rate-error region increases since the achievable bound with feasible blocklength set to be large N is more accurate. As D moves close to D_m , the coefficient γ_L approaches $1/2$ according to (??). However, it switches from $1/2$ to 1 when D exceeds the threshold, which leads to the $1/N$ sharp increase in the rate-error tradeoff shown in Fig. ?? Then this boundary is invariant of D , indicating that the S&C performance is decoupled.

As D moves close to D_m , the coefficient γ_L approaches $1/2$. The area of the rate-error region increases with the blocklength when the performance tradeoff between S&C vanishes in the large blocklength regime due to the blocklength N tends to infinity, this boundary of the achievable rate-error region approaches the horizontal line with height $\log_2(1 + N\rho|h|^2/\sigma^2)$. The area of the rate-error region increases

V. CONCLUSION

This paper provides a characterization of the performance tradeoff between S&C in a SISO ISAC system with finite blocklength where the rate-error tradeoff is introduced as the performance metric. In particular, we derive the achievability and converse bounds for the rate-error tradeoff, after which the asymptotic analysis is performed to show that the performance tradeoff vanishes as the blocklength tends to infinity. Finally, our theoretical results are verified by the numerical experiments. Future work will focus on obtaining tighter bounds for the rate-error tradeoff as well as the extension to MIMO ISAC systems. The contributions of this paper give insights to the understanding of the fundamental tradeoff and the future system design in ISAC.

Fig. 4: The achievable rate-error region with the varying blocklength

with the blocklength N , since the performance tradeoff between S&C vanishes in the large blocklength regime. As the blocklength N tends to infinity, the boundary of the achievable rate-error region approaches the horizontal line with height $\log_2(1 + N\rho|h|^2/\sigma^2)$.

V. Conclusion

This paper provides a characterization of the performance tradeoff between S&C in a SISO ISAC system with finite blocklength where the rate-error tradeoff is introduced as the performance metric. In particular, we derive the achievability and converse bounds for the rate-error tradeoff, after which the asymptotic analysis is performed to show that the performance tradeoff vanishes as the blocklength tends to infinity. Finally, our theoretical results are verified by the numerical experiments. Future work will focus on obtaining tighter bounds for the rate-error tradeoff as well as the extension to MIMO ISAC systems. The contributions of this paper give insights to the understanding of the fundamental tradeoff and the future system design in ISAC.
